ACKNOWLEDGEMENTS

Many people were indispensable in allowing me to complete this study. I am indebted to Mr. Aunri Gagnon of the Algonquin Radio Observatory, Ottawa, Canada, for the 10.7 cm solar scans and Ms. Helen Coffey, Major Bruce D. Springer, and especially Mr. Ronald W. Buhmann at the National Oceanic and Atmospheric Administration World Data Center, Boulder, Colorado, for the SOON data. Guidance and explanations of the systems for collecting these data were graciously provided by Dr. Morley Bell at Algonquin and Mr. Arnold Star at the Holloman AFB, New Mexico, SOON site. I must also thank all of the members of the first Graduate Space Operations class at the Air Force Institute of Technology for their invaluable support, in particular, Captain John D. Rask and Captain Robert I. Boren. Additionally, I must acknowledge the tireless efforts of Major James J. Lange for helping me to understand the physical phenomena involved in the project and Captain Brian W. Woodruff, my advisor, who always kept me moving in the right direction. Finally, I want to thank my friend, Captain Brian E. Dieffenbach, who helped me keep my perspective throughout the project.

Craig A. Pus

AMBd ABSTRACT

→ Using a statistical regression model, a relationship was found between the area of solar active regions (bright in hydrogen-alpha, $\lambda = 6562.8 \text{ \AA}$ in the visible) and their 10.7 cm radio emission. Data used in this analysis were the brightness-area histograms obtained from the Solar Observing Optical Network (SOON) and daily drift scans obtained from the Algonquin Radio Observatory, Ottawa, Canada. This data, for the period 1 May through 16 July 1978, was used to develop the following relationship:

Algonquin Scan Peak Value =

$$.88782838 + .00025237604 \text{ (Calibrated SOON Area)}$$

with a correlation coefficient, r , of .88509. Future models for predicting the 10.7 cm solar flux are theorized based on the established relationship.

C

CORRELATING RADIO EMISSIONS WITH VISIBLE EMISSIONS FROM INDIVIDUAL SOLAR ACTIVE REGIONS

I. Introduction

Background

A definite correlation exists between hydrogen-alpha active regions on the sun and the 10.7 cm solar radio flux observed at 1700Z daily at the Algonquin Radio Observatory, Ottawa, Canada (Refs 7:454 and 8:126). Since this correlation has been shown, officers at the Solar Forecast Center, Air Force Global Weather Central (AFGWC), Offutt Air Force Base, Nebraska, want to predict the actual 10.7 cm flux from observations of active regions with the Solar Observing Optical Network (SOON). Indeed, one of the ancillary purposes of this research will be to determine the feasibility of using SOON data as an input to a predictive model. The primary purpose of this research, however, will be to find a relationship between the Algonquin drift scans of the sun and the data from the SOON network. The SOON network has only existed since 1977, and to date little of the data has been used for any research purposes (Ref 38). The underlying rational for this study is found in an article by Covington, Legg, and Bell describing the relationship between hydrogen-alpha filtergrams - west drift scans of the sun (Ref 9:471-473). Instead

of using hydrogen-alpha filtergrams, this data is replaced with the SOON data which is also centered on the hydrogen-alpha wavelength ($\lambda = 6562.8 \text{ \AA}$).

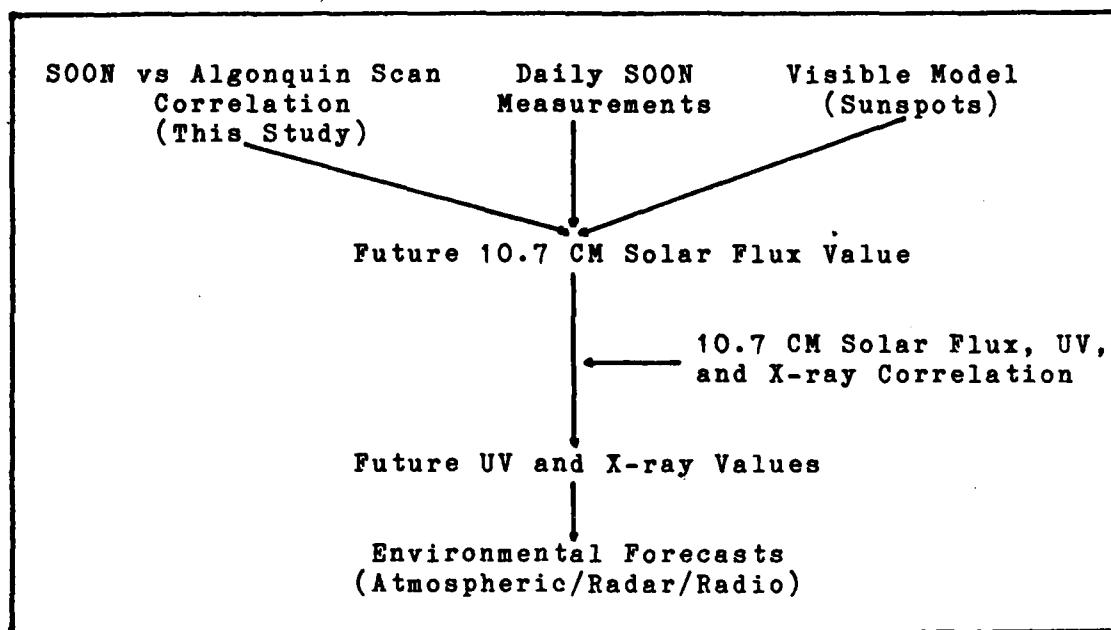

Figure 1. Prediction Hierarchy

Knowing active region area and sunspot activity, forecasters want to develop an accurate way of predicting the 10.7 cm flux from these features when they reappear after rotating out of the field of view of the earth. This involves roughly a 13-day lead-time depending on the region's latitude. Such a time development model of visible active regions would rely heavily on the proposed relationship being investigated by this study as well as current models of sunspot movement, development, and decay. These components could be synthesized into a predictive routine for the 10.7 cm solar flux with roughly a 13-day lead-time.

Prediction of the 10.7 cm flux is not the end product; rather, it is used as an indicator of solar ultraviolet (UV) and X-ray radiation. There is a documented correlation between the 10.7 cm radio flux, solar UV and solar X-ray radiation (Ref 11:2). The 10.7 cm flux is used as a predictor for these latter two radiations because 10.7 cm data can be collected on the ground whereas UV and X-ray measurements must be done above the atmosphere. Being able to predict the 10.7 cm flux in advance would allow similar lead-time prediction of UV and X-ray wavelengths. Of primary interest are the effects of UV and X-ray radiation on the earth's upper atmosphere. These include the density of the upper atmosphere which determines the drag experienced by low altitude satellites. Also, UV and X-ray radiation affects the structure and conditions of the ionosphere. Many agencies are very concerned with ionospheric effects because of the way they influence radar and radio transmissions. Figure 1 highlights these interrelationships.

Now, with these factors in mind, a relationship must be developed between the SOON data and Algonquin Radio Observatory drift scans of the sun which can be used in future studies to predict the 10.7 cm flux using SOON data. This involves exploring growth and decay trends expected in the size of bright active regions from one day to the next, how the rotation of the sun affects apparent area of these regions at the earth due to foreshortening, viewing position (accounting for inclination of the earth's orbital plane and tilt of

the solar axis), latitudinal affects on the sun itself, and if the active region is above or below the solar equator. The above considerations can be gleaned from brightness-area histograms from the SOON network. The histograms are recorded daily for selected active regions on the sun. All of the above factors can be roughly accounted for based on a composite of the individual histograms.

Statement of the Problem

Data concerning the relationship between hydrogen-alpha active regions and the total solar 10.7 cm radio flux has existed since 1977, but no work has been done to relate these two data bases in the short term on a region by region basis. Most studies, none involving SOON data, deal with longer periods such as a month and the 11 year solar cycle.

Objective of the Research

The objective of this research will be to develop a relationship between SOON data and Algonquin drift scans which can be used as the basis for a forecast model for the 10.7 cm radio flux using brightness-area histogram scans from the SOON network. Basic hypotheses involved concern whether or not the SOON data is related to the Algonquin scans and whether it is significant enough to be used as a predictive tool.

Methodology

The objective of this study will be accomplished by analyzing data comprised of SOON brightness-area histograms

and 10.7 cm radio flux data from the National Oceanic and Atmospheric Administration (NOAA), Boulder, Colorado, and Algonquin Radio Observatory, respectively. The histograms and solar scans, though taken at different locations, are done at roughly the same time and can therefore be compared directly. A regression model will be developed with the data. The model will be run with the help of SPSS (Statistical Package for the Social Sciences) regression packages and the CYBER 1700 computer.

Limitations

As with any new system, SOON has some inherent limitations. In the preliminary stages of this research, it was hoped that digitized pictures of the solar disk would be available for analysis. This, however, was not the case. The sun is divided into regions for SOON observation, and all are not looked at daily. In fact, the SOON data available is limited to active regions on any given day. This means that the entire solar surface will not be available for analysis every day, and that a composite of available histogram data will have to be used to formulate a crude solar image for comparison with the solar scan data. Additionally, there are some gaps in the data due to cloudy weather conditions at the SOON and Algonquin sites and days when observations could not be made because of technical difficulties (Refs 4 and 30). For active regions near the limbs of the sun, large errors are introduced into the histogram data if the dark background sky

is included in the measurements. Data is generally recorded for regions as they move across the entire solar disk but is most accurate for those regions lying 65° E and 65° W of the central meridian (Ref 4). Therefore, most of the data from the solar limbs will have to be eliminated.

With these limitations in mind, the research was further constrained by the availability of the SOON data itself. Since the system is relatively new, little use has been made of the data. Because of this, most of the data is in raw form, requiring much time and effort to reduce to a usable form (brightness-area histograms). To date, the only available SOON data in reduced form covers the period from May 1978 to December 1978. This data base must be further reduced since only data corresponding to the 1700Z Algonquin drift scans is relevant. Therefore, of the available data taken throughout the day, only the readings (histograms) as close to 1700Z as possible for each region observed, will be used in this study. Unfortunately, there is one further problem. Mr. Arnold Star, Detachment 4, 3rd Weather Wing, Holloman AFB, one of the observer/collectors of the SOON data, informed me that he had serious doubts as to the validity of the data for this period in its present histogram form. Mr. Star feels that the data for the May 1978-December 1978 period may not be standardized. As he explained, a videometer is used to break the image into 64 shades of gray. The pixels in each band are then counted and equated to an area. The greatest number of counts should be centered on the background level to obtain a

normalized quiet sun level. Early readings (including the May 1978-December 1978 period) were not all normalized to the same quiet sun level. Some were normalized to 10 and some to 12 (on a 0-64 scale). Mr. Star suggested that the data be further normalized to account for all of these effects (Ref 39). This exercise is beyond the scope of this study. Instead, the data will be used as is. More accurate correlations and predictions will have to be the result of future studies in this area using later data that is more standardized.

One other obvious limitation with this technique is the time involved in getting the data into a usable format. For short-term predictions, the speed with which the data is processed and made available for analysis will have to be greatly increased. Otherwise, the SOON data will be of little practical value for short term predictions.

There are no readily apparent problems with the 10.7 cm solar flux data from the Algonquin Radio Observatory. This data has been used as a basis for prediction of the 10.7 cm solar flux since 1947. It has been the standard basis for all models with earth-based parameters (Ref 11:2).

II. Historical Survey

SOON Data

The Solar Observing Optical Network is one of the newest means by which solar related data can be collected on hydrogen-alpha active regions. This worldwide system was developed and is operated by the United States Air Force (USAF) Air Weather Service. As of now, there are four sites designed to collect data. Data collection began at Holloman AFB, New Mexico, in November 1977 and was soon supplemented by data from Palehua, Oahu, Hawaii, December 1977, Ramey, Puerto Rico, February 1979, and Learmonth, Australia in 1979. A fifth site has been proposed for somewhere in the Middle East.

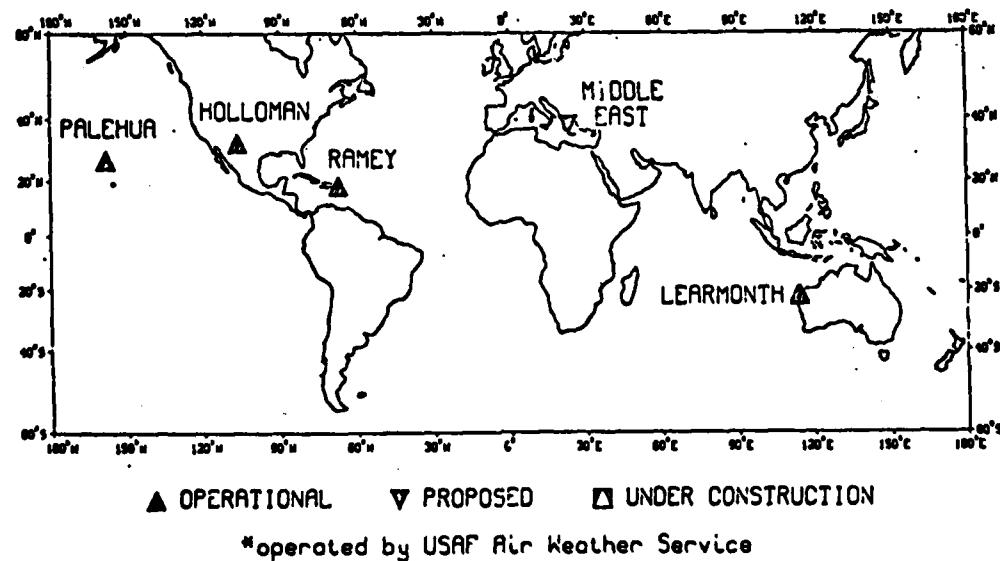

Figure 2. Solar Observing Optical Network (Ref 4)

The observing schedule of active regions at each observatory is decided upon by the duty observer, with suggestions from the parent site at Holloman, depending on the level and type of activity and the needs of real-time services; this determines the order of data on magnetic tape and companion photographic film.

As the system is so new, extensive work is still being done to determine how best to use all of the data. As uses are developed, more and more of the data will be processed into the final outputs, which consist of brightness-area histograms (see Figure 3), flare time-histories, as well as

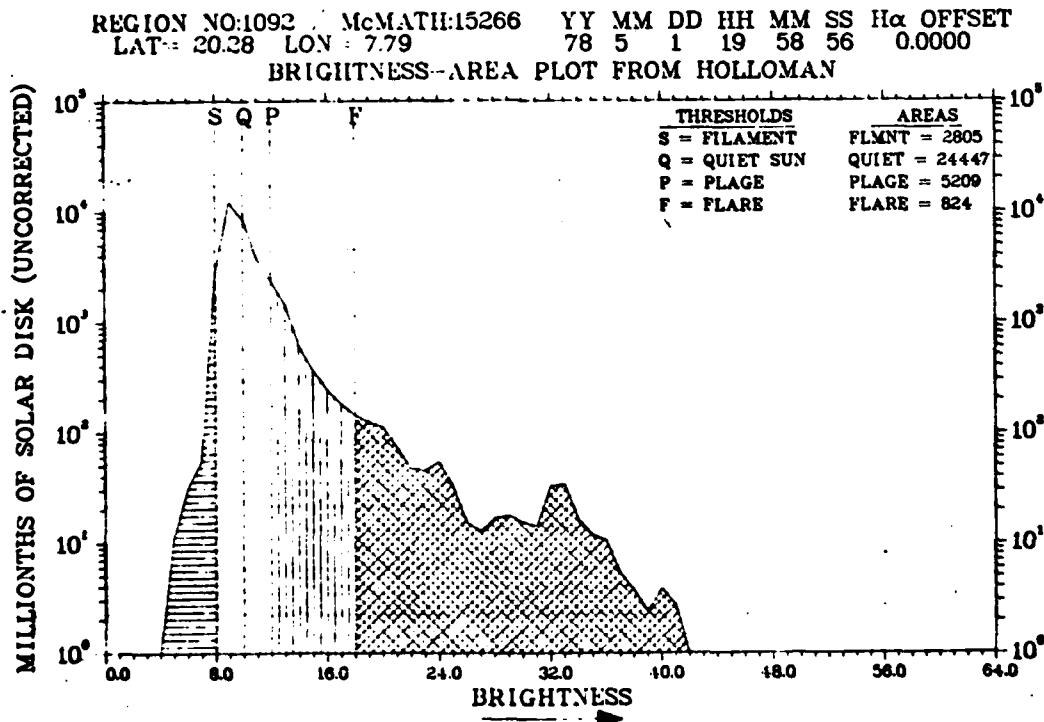

Figure 3. Brightness-area scan of an active region (Ref 30:1)

photographs of the corresponding solar phenomena. The brightness-area histogram depicted in Figure 3 is a graphical representation of all the data provided in each SOON histogram record set. Each record set could be used to construct a histogram in this form. The system is calibrated such that if the quiet sun mode occurs in bin 10 (bin equals 0-64), bin 20 is twice as intense and bin 30 is three times as intense. Borrowing from the SOON descriptive pamphlet:

The basic SOON telescope is a 25-cm evacuated refractor mounted on a polar axis using a monochromatic filter (0.5A bandpass) centered on the Hydrogen-alpha absorption line of the solar spectrum. A built-in minicomputer totally directs the collection of all data.

The digital H-alpha brightness-area data are the major data product from a SOON telescope. These data present brightness versus area information from particular flare-producing regions on the sun. The brightness ranges from dark shades, indicating relatively cool absorbing plasma, to very bright shades indicating hot emitting plasma, i.e., flares. Sixty-four shades of brightness are graphically presented on the horizontal axis of the brightness-area plot. The height of a brightness column represents the uncorrected area of a given brightness shade summed over the entire region. The observer sets threshold values for filament, quiet sun, plage, and flare according to observing conditions, and the corresponding areas in millionths of the solar disk (not corrected for foreshortening) are calculated and recorded on this plot. The automated capability of the SOON telescope system allows brightness-area information to be collected from as many as six regions per 5-sec interval. The system is usually programed to collect 1 to 3 brightness-area scans per minute from each selected region (Ref 30).

The 10.7 CM Solar Radio Flux

Radio emissions from the sun range from 8 mm to 15 m in wavelength of which the 10.7 cm wavelength (2800 MHz) is only a part (Ref 3:189). This band is essentially blackbody radiation from high temperature regions and varies slowly between fairly narrow limits (Ref 28:30). Also, part of the 10.7 cm radio flux is emitted by spiraling electrons in the sun's magnetic field and is sensitive to the strength of the magnetic field so that active regions with strong magnetic fields may emit stronger in the 10.7 cm radio flux than older less active regions (Ref 13:21). These radio emissions are made up of three components;

a fairly constant basic component (quiet sun emission), occasional bursts of different types and durations, closely associated with solar flares, and a slowly varying component...exhibiting roughly a 27-day recurrence period (Ref 10:734).

The basic component can be found by

plotting the apparent temperature vs projected sunspot area and extrapolating to zero sunspot area...the slowly varying component arises from regions at a height of 100,000 km above the photosphere and [is] associated with chromospheric faculae (Refs 3:189 and 35:223).

This has been verified since, as the sun rotates and varied size spots and spot groups move across the solar disk, the slowly varying component varies accordingly. Thus, the slowly varying component shows a close association with sunspot number and exhibits the 27 day variation (Ref 35:225).

Basically then, research indicates that, over and above the background basic component, the slowly varying component of the 10.7 cm radio flux is emitted from the corona and has a

10.5 year period associated with it (Refs 11:1,8;6:31;8:129; and 28:33). Often, the three components described above are not broken out in this manner. Only two components are discussed, active and background (Ref 1:3232).

With these regions and components in mind, a brief discussion will be made of the methods used and values obtained for the solar flux. The antennas used to obtain the radio flux are of low resolution so that the antenna beam covers the whole solar disk and the values obtained represent an average over the solar disk (Ref 15:4). These values have ranged from 67×10^{-22} Watts/m²/Hz to 380×10^{-22} Watts/m²/Hz (Watts/m²/Hz=Watts m⁻²Hz⁻¹=Jansky) since 1947 (Ref 36:Section 5,1) never falling below 65×10^{-22} Watts/m²/Hz (Refs 11:4 and 8:127). Richards has noted that "the values may differ by as much as 100 [$\times 10^{-22}$ Watts/m²/Hz] from one day to the next near their maximum, and generally by no more than 6 or 10 [$\times 10^{-22}$ Watts/m²/Hz] near their minimum values" (Ref 36:Section 5,1).

The 1700Z radio measurements for this study were obtained from the Algonquin Radio Observatory, Ottawa, Canada, with the cooperation of Mr. Aunri Gagnon. The drift curves are taken with a multi-element interferometer capable of providing multiple fan beams, 1.5' of arc east-west by 2° north-south, sufficiently separated so that only one response falls on the sun at any one time. When this is used in conjunction with an offset grating of four elements, a compound interferometer results capable of achieving a single-lobed fan beam with 15" arc east-west (Ref 9:465-466). This resolution produces scans

like the one depicted in Appendix B (Figure 7) which is representative of all the Algonquin data. The peaks represent radio emissive regions associated with plages and active regions.

10.7 CM Solar Radio Flux Uses

The 10.7 cm solar radio flux data, having the advantages of being measured on the earth's surface and for the longest period, are being used in many ways. Because of its long history of careful observation (Ref 19:327) and its use as a general predictor of solar radiation in Extreme Ultraviolet (EUV) and X-ray wavelengths (Refs 19:327;18:10; and 11:2), the 10.7 cm flux has evolved as a well-entrenched parameter that is used by a large number of radio communicators and upper atmospheric modelers for a variety of operational applications (Refs 19:327;14:1-2; and 8:131).

Usefulness. Descriptions of the usefulness of this parameter range from it being an excellent predictor of solar activity (Ref 28:33) to an opinion by one expert that its time has passed (Refs 12 and 13:21) and new and better methods should be adopted for more accurate prediction. Richards, commenting on the 10.7 cm flux, went as far as to say that "the yearly mean is all that can be reasonably predicted since the shorter period fluctuations are quite irregular and follow no pattern" (Ref 36:Section 5,1).

Predicted Values. There are similar feelings concerning the spectrum that the 10.7 cm flux is used to predict. In

regard to EUV, many scientists feel that the ten-centimeter flux is

too gross a parameter to accurately evaluate the state of the ionosphere and upper atmosphere and that more specific measurements in the EUV would improve the operational models. However, the lack of a consistent and on-going EUV observational program and the expense and disruption of redoing present operational models (Ref 19:327)

precludes eliminating the ten-centimeter flux as a model input. Until the advent of routine exoatmospheric EUV and X-ray satellite measurements, the 10.7 cm flux was seen as a fairly accurate predictor of these events (Ref 28:33). Now, however, since such measurements are more routine, numerous studies point out that the 10.7 cm flux is not a very accurate predictor at all (Refs 19:327;1:3231;12; and 13:21) and should not be relied upon for accurate ionospheric, upper atmospheric, and satellite drag models. Certain correlations are very good such as the one between the 10.7 cm flux and atmospheric density changes resulting from heating (Ref 1:3231) but this is an aggregate effect over a relatively long period. Whenever 10.7 cm flux data is smoothed, it generally gives a fairly good correlation in the long term but short term correlations are very poor (Refs 23:1;13:22). In this regard, there are documented effects due to solar rotation and whether measurements are taken near solar maximum or minimum (Ref 1:3231).

When dealing specifically with UV, Donnelly points out that:

sunspot number and 10.7 cm solar radio flux are useful as a general guide to the level of solar activity. However, they are not precise indications of the solar UV flux.

They can give very erroneous UV estimates when they are used for particular days rather than for average effects (Ref 13:21).

He goes on to say that

the 10.7 cm radio flux and sunspot number are of course correlated with the solar UV flux because all three are generally related to the number and size of active regions. The more smoothing applied to the data, the higher the correlation because the differences due to CMD [Central Meridian Distance] and magnetic field orientation and strength distribution among active regions become smoothed out to average values (Ref 13:22).

Such correlations are also found when 10.7 cm flux and flares are considered. Mohler has shown that the 10.7 cm daily flux provides a general guide to flare activity but that the accuracy varies for different flux levels (Ref 29:2). The same general finding applies to the correlation between the quiet sun soft X-ray flux and the 10.7 cm radio flux as investigated by Gibson and Van Allen (Ref 18:8-10). Finally, Bossy and Nicolet use the 10.7 cm flux as an input for their predictive model of Lyman-alpha irradiance (Ref 2:907).

From the foregoing survey, it can be surmised that better predictors are available with documented validity. They will eventually work their way into various predictive routines. But, until their data bases are significant and continuously recorded, as the Ottawa 10.7 cm flux data, their usefulness will be limited.

10.7 CM Solar Radio Flux Predictive Models

A result of the relative newness and lack of processing of the SOON data, coupled with numerous conversations with officials directly involved with collecting and processing the

data, it is clear that no one has attempted to develop a prediction scheme for the 10.7 cm solar flux using the SOON data (Refs 4;17; and 22). There have, however, been numerous other predictive techniques developed to predict the 10.7 cm flux in the long (up to a year), medium (month), and short term (days). By using SOON data, forecasters hoped to eliminate some of the observer dependent subjectivity associated with existing 10.7 cm prediction methods.

Cautions. The relationship between the Zurich relative sunspot number, plage index, and the 10.7 cm flux has been established and used by many scientists to predict the 10.7 cm flux (Ref 7:454 and 8:126). A brief review of efforts from the long to short term follows some appropriate cautions from Yu I. Vitinskii, an expert in solar activity forecasting. Vitinskii points out that any prediction based on sunspots and sunspot areas suffers from inherent inaccuracy due to visibility conditions and limb effects. Atmospheric conditions and proximity of spots to the solar limbs add a great deal of uncertainty to the number and area of spots. If these parameters are used in prediction models, the output is less than optimum since errors are compounded. This is one reason monthly and yearly values are preferred so the values can be smoothed to reduce inaccuracies (Ref 42:5). Vitinskii's observation related to these long term techniques is often quoted: "we have shown that the reliability of the results obtained using these methods still leaves much to be desired" (Ref 42:103).

Long Term Techniques. The extensive effort of Slutz et al is an example of using smoothed Zurich 13 month mean sunspot numbers to predict the 10.7 cm solar flux. This study was supposed to be an aid in solar activity prediction by first developing a model to predict sunspot numbers several years in advance and then use these values to predict the corresponding 10.7 cm flux value. An integral part of the study was therefore to determine which of several mathematical expressions best described the relationship between the 10.7 cm flux and the Zurich 13 month mean sunspot number. The results indicated that a second order equation was acceptable to represent the relationship over the 12 month period since, up to the time of the study, little consideration had been given to this relationship for periods less than one-half of a solar cycle (1 cycle is approximately 11 years) (Ref 37:87). The long-term technique advocated in this study was considered valid enough to be used as the 10.7 cm flux prediction method in NASA's Solar Activity Prediction of Sunspot Numbers (Ref 24:1) and its subsequent verification (Ref 32). Note, however, that this model and its applications are used in the long term for the 13 month smoothed 10.7 cm flux value and do not impact on the present study.

Some atmospheric density and satellite drag modelers have also evolved their own methods for predicting the 10.7 cm flux as well as other parameters needed in their models. Richards developed a piece-wise linear model for different levels of the smoothed sunspot number (R_z):

$$0 < R_z < 30 \quad \bar{F}_{10.7} = 68 + 0.60R_z \quad (1)$$

$$30 < R_z < 70 \quad \bar{F}_{10.7} = 60 + 0.825R_z \quad (2)$$

$$70 < R_z < 200 \quad \bar{F}_{10.7} = 50 + .967R_z \quad (3)$$

where $\bar{F}_{10.7}$ is the yearly mean flux value (Ref 36:Section 5,2). Slutz' colleagues, Stewart and Leften, compared the results from their final second order equation for predicting the yearly mean 10.7 cm flux value (ξ_{12})

$$\xi_{12} = 63.7451 + 0.728015R_{12} + .000890443(R_{12})^2 \quad (4)$$

with Richard's equations values and found the results to be very similar (Ref 37:107). Again, the long term nature of these studies negate their usefulness for short term predictions.

As discussed by Gibson and Van Allen, Kraus determined two components of the 10.7 cm flux in his book Radio Astronomy (Ref 26:Chapter 3). He showed that the radio flux density at earth from an optically thin emitting region is

$$P = 2.7 \times 10^{-48} T^{-1/2} S \quad (5)$$

where P is the radio flux density at 10.7 cm at 1 Astronomical Unit in units of 10^{-22} Watts ($m^2 Hz$) $^{-1}$, T is the electron temperature in $10^{60} K$, and $S \equiv \int N_e^2 dV$, the volumetric emission measure in cm^{-3} (N_e is the electron number density in cm^{-3} and dV is the element of volume in cm^3) (Ref 18:15). The volume integral is taken over the emitting region, assumed to be at the same temperature T throughout. For an optically thick

emitting region

$$P = 1.1 \times 10^{-19} AT \quad (6)$$

where A is the projected area in cm^2 of the outer surface of the emitting region as viewed from earth (Ref 18:16). These equations were developed using data from a limited period where P ranged from $90.1 \leq P \leq 261.7$. It seems as though these equations could be used in the short term depending on variable availability, but this was never done on a regular basis.

Medium Term Techniques. Jack Sill at the Smithsonian Astrophysical Observatory developed the following relationship for use by NOAA to predict the monthly flux based on the smoothed Zurich relative sunspot number 13 month average. This technique uses a least-square regression model to generate the predicted smoothed \bar{R}_{13} values which are then used as inputs to linear regression equations to compute $\bar{F}_{10.7(13)}$ solar flux values (Refs 19:332 and 16:380)

$$\bar{F}_{10.7(13)} = 49.4 + 0.97\bar{R}_{13} + 17.6\exp(-0.035\bar{R}_{13}) . \quad (7)$$

This equation was used by Holland, Rhodes, and Euler to extend values of the 10.7 cm flux back to 1749 in order to develop a predictive model of solar activity (Ref 23:2).

Short Term Techniques. For short term predictions, forecasters at the Global Weather Central initially used a regression technique to establish a trend based on the last 3 solar rotations (weighted toward the most recent rotation) and

the trend for the past two or three days of the current rotation. Then, using the east-west 10.7 cm scans from the National Research Council, Ottawa, to establish the relative location of radio plages and thereby estimate the effects of solar rotation, they varied their prediction based on experience (Ref 19:341 and 22). This procedure may lack rigor but until that time provided the only very short term forecast of 10.7 cm flux (see Appendix A for sample output) (Ref 28:48).

The most rigorous models used for predicting smoothed values for the 10.7 cm flux and geomagnetic indices are SUNSPOT developed by the NASA Marshall Space Flight Center, the Air Force Global Weather Central 27-day regression forecast subroutine, and EST10 developed by NOAA. SUNSPOT is used for statistical estimation of future expected values of the monthly 10.7 cm solar flux and the 5 month smoothed flux values ($F_{10.7}$) (Ref 41). The AFGWC 27-day regression forecast subroutine predicts the 10.7 cm solar flux for the 27 days following the current day's 10.7 cm flux (Ref 22). EST10 is used to estimate the 10.7 cm flux value for 1, 2, and 3 days into the future. It must be continually updated and run in order for the short term forecasts to be accurate. To date, this is the most refined short term predictive tool. In fact, it virtually ignores any long term effects and produces very subjective results since the operator can change the inputs based on his experience (Ref 22). As with each of the other models, these procedures do not rely on any SOON data inputs.

III. Methodology

Data Reduction

Before the data could be used, it had to be reduced into formats for comparison. The Algonquin data, in graphic form, of solar scans, could be used for direct comparison with the SOON data. The scans are taken of the sun from the west limb to the east over a period of about two to four minutes daily at 1700Z (Ref 9:465 and 27:749). See Appendix B for an example. The scans are of the apparent sun without correcting for the solar tilt in relation to the ecliptic (P angle) or the heliocentric location of the sun's center (B_o and L_o). These angles did have to be considered when trying to make a direct comparison with the SOON data since P, B_o , and L_o are accounted for in the region identification of this data. For the purpose of this analysis, P, B_o , and L_o were considered constant for the entire day. In the ephemeris they are for 0000Z whereas they are used for corrections to measurements taken at 1700Z (Ref 40:350-353). Small variations produced by this difference were not considered significant.

Each brightness-area histogram from the SOON network has a specific format (See Appendix C). The first card of a four or eight card sequence (single or double length histogram, respectively) has all the identifying information for the particular region being examined and calibration data for

being able to relate each histogram record to the others. Since, on a given day, in the time frame of interest (near 1700Z), the SOON instrument can sample numerous regions many times each, the optimum approach was to average the data for each region observed. The SOON program was written for this purpose. This program not only averages the daily readings near 1700Z for each region observed, but also corrects the region area to account for foreshortening (See Appendix D) and performs a coordinate transformation on the original SOON latitude and longitude to get the data points in the reference frame of the Algonquin data (Ref 25:8-13). See Appendix E for a derivation of the transformation algorithm used. This transformation allows for direct comparison of the SOON bright regions with the bright region peaks on the Algonquin scans and provides a rough idea of the location of the region in terms of solar radii distance from the central meridian. This is done with a spherical to rectangular coordinate transformation (Ref 34:35-38).

In order to validate the SOON program, a sample set of data was selected to exercise the various aspects of the program. As with the real data, it allowed for summing the areas above the quiet sun level for a rough approximation of activity in each region measured, selecting the appropriate daily P, B_o , and L_o readings from the ephemeris, deciding whether a single or double length histogram was being read (column 1 of card 10), reading the region identifier, day, time, latitude, longitude, wavelength offset, quiet sun level,

and calibration constant. Most of these features are then used in the program to obtain summary data or as checks to determine if the data set should be discarded (for example, a wavelength offset other than zero causes the histogram to be purged; wavelength offset gives an indication of how far from the hydrogen-alpha centerline the readings are. If it is not zero, additional corrections must be made to the readings which were beyond the scope of this study). After accounting for all of these factors, the data was in a form for direct comparison.

Data Comparison

Now, having summary data by each method, a comparison was made region by region for each day to determine if bright regions on the SOON scans corresponded to bright areas (in longitude only) on the Algonquin plots. Since the Algonquin data can only give an indication of the relative distance of active regions from the solar central meridian, a rough comparison of longitudes is possible but not pinpoint accuracy in either latitude or longitude. This becomes apparent when looking at the Algonquin scans. In reality then, the latitude reading produced by the SOON program is unnecessary but is included for completeness.

As previously mentioned, available data from the SOON network was limited to the May to December 1978 time frame. Of this, only data from 1 May through 16 July 1978 could be used in the analysis. Additional data was unavailable due to

the time and expense involved in processing it.

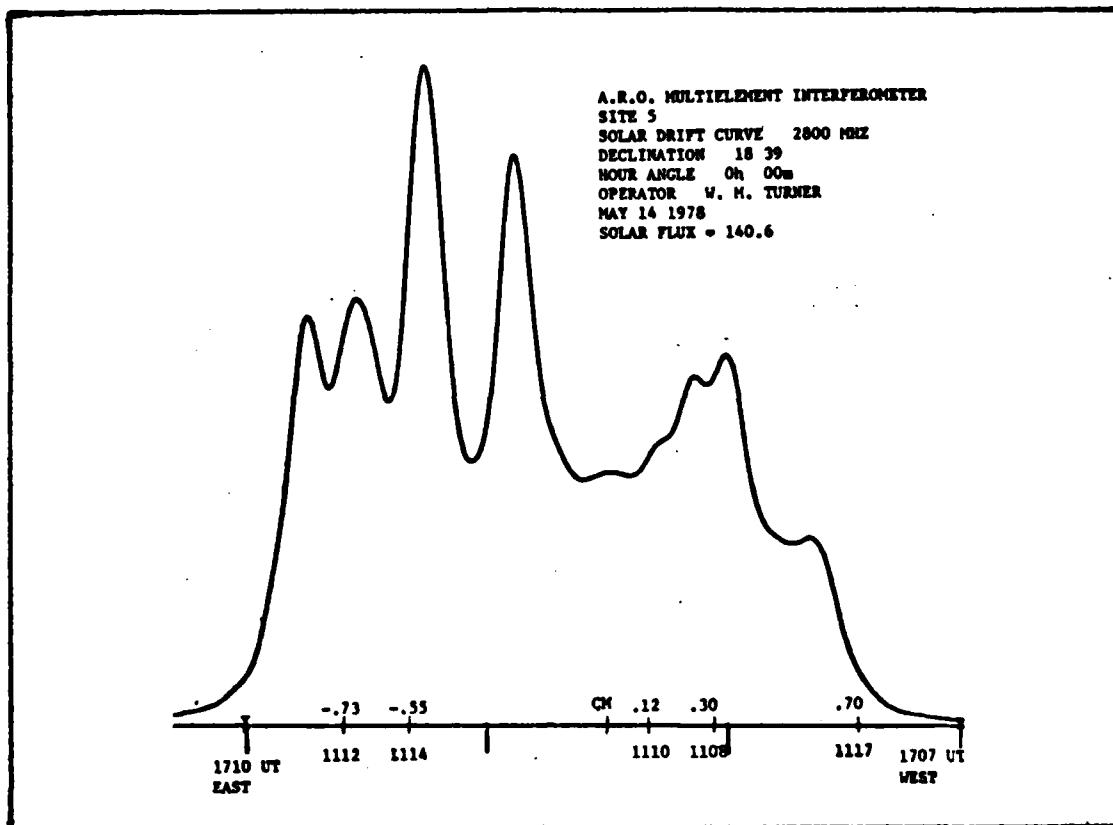

Figure 4. Algonquin Solar Drift Scan - 14 May 1978

Table I

Sample SOON Program Printout - 14 May 1978

| SUMMARY TABLE FOR DATE: 780514 IS: | | | | | | | | | | |

Figure 4 and Table I will help in understanding the methodology involved. This data set is typical of all the data reviewed. The solar drift curve is a reduction of the

actual curve received for 14 May 1978. The east and west solar limbs are identified by the tick marks labeled 1710 UT and 1707 UT, respectively. The USAF numbered regions and percentage of solar radii for each, identified by the SOON data, are also shown. CM is the approximate location of the central meridian. The summary table for 14 May 1978 is representative of the output from the SOON Program. It identifies the USAF numbered regions observed each day (REGION), their latitude and longitude in the heliocentric frame of the sun (LAT and LONG), total area of all histograms of the same region (TOTAL AREA), number of histograms recorded for each region (OBSV), the average area for the region observed (AVG AREA), the average area corrected for foreshortening (COR AREA), the new latitude and longitude in the Algonquin reference frame (NLAT and NLONG), and the percent of solar radius where each region lies in reference to the solar central meridian (SOLRAD).

One notable characteristic is the second highest spike on the Algonquin plot just to the east of the central meridian. Throughout all of the scans that tracked this feature across the sun, there was never a corresponding SOON region that could be matched with it. This is to be expected since there are some features detected by one method that may not have a match in the other data. Based on scans that came before this one, the various spikes on the Algonquin plot could be correlated with active regions identified by the SOON data. Note that Region 1099 was eliminated immediately since its

longitude was far beyond the 65 degree limit and resulted in an apparent solar radius of greater than 90 degrees. In comparing the above data sets it is apparent that the SOON data indicates large bright areas at 73 and 55 percent of a solar radius east of the central meridian and 12, 30, and 70 percent of a solar radius west of the central meridian. To arrive at the locations on the 10.7 cm radio drift scan plot for these points, the distance between the indicated east and west limbs was divided in half, and these percentages were applied to this figure. This procedure was considered reasonable since the SOON data was unitized to solar radii by setting $R_s = 1.0$ as described in Appendix E. As theorized, spikes corresponding to each of these identified regions exist on the Algonquin plot.

This method of rough comparison substantiates the existence of a correlation which appeared between a majority of the daily scans and SOON summary printouts. From the data on successive days, a given active region could be tracked across the sun at roughly the correct solar rotational velocity for the region's latitude (Ref 17:31). The fact that both the Algonquin scans and SOON data depicted this movement further reinforces the existence of a relationship between the phenomena. A point to remember about the Algonquin data is that, due to the sensitivity of the equipment, it must be adjusted to keep each day's reading from being too great. Therefore, if a very bright region is in the scan, the gain must be reduced to keep that region within the bounds of the

equipment. When the active region rotates out of the field of view of the instrument and the instrument gain is increased, specific features may become apparent that had been obscured.

The calibration constants in Appendix B (Table II) make all the 10.7 cm drift scan readings comparable and were applied before data analysis. This was done by measuring the peak in centimeters (scale not important) corresponding to an active region identified by the SOON equipment. The values obtained were then divided by the calibration constant for the day under study to arrive at the numerical input from the Algonquin data that would be compared with its corresponding region area as defined by the SOON data.

Data Analysis

Once both data sets were reduced to this point, they were in a form for direct comparison to determine if a relationship existed between them with the hope of finding a definite mathematical relationship. If such a relationship could be established, it could then be used for developing more accurate forecasting models of the 10.7 cm solar flux. This then, is the major aspect of this study; to determine if a relationship exists between the irradiance of the active regions identified by the SOON data and the features identified by the Algonquin plots. To attempt to establish this relationship, the magnitude of the Algonquin plot peak values corresponding to active SOON regions were measured as mentioned previously. The SOON corrected areas made up the other

half of the data. Areas were used since they represent the relative brightness of each region above the quiet sun level that correspond to active regions on the Algonquin plots. All told, there were 180 data points (individual features in both the Algonquin and SOON data) available. These represented 53 distinct USAF numbered regions in a two and a half month period. Of these, 38 SOON data points and their corresponding Algonquin plot values had to be discarded because they were too far into the solar limbs (greater than 80 degrees east or west of the solar central meridian). Even though three of the data points had longitudes greater than 65 degrees, they were left in because they were only slightly greater than 65 degrees.

Model Development

The final pairing resulted in 142 points for input into the data analysis programs (see Appendix F). Though more would have been desired, this sample should be enough to validate or refute the existence of a relationship between the SOON and Algonquin data. Since there was only one feature from each of the data sets, a simple linear regression routine was used to compare the data (Ref 5:1-22 and 33:320-349, 293-300). The basic linear regression model used was

$$Y = a + bX + \epsilon \quad (8)$$

where a and b are the intercept and slope, respectively, and ϵ is the random error with mean zero and variance σ^2 . The model further assumes:

1. The sample is random,
2. The dependent variable, Y (Algonquin scan value), is drawn from a normal distribution for any given value of X (corrected area from SOON),
3. The regression of X and Y is linear,
4. All of the Y values have the same variance, and
5. The random errors, ϵ_i , are independent of each other.

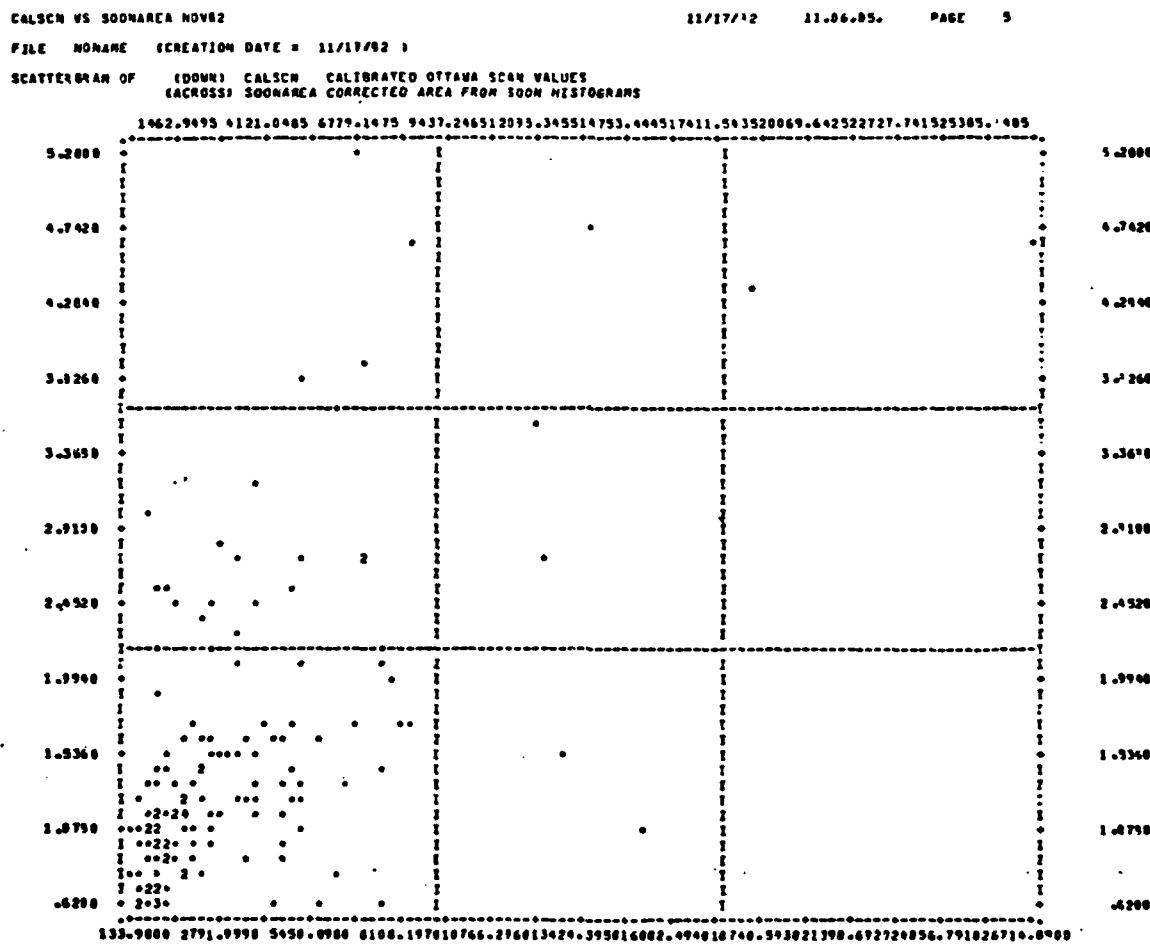

Figure 5. Scattergram of CALSCN versus SOONAREA

The first attempt at a regression equation relating X and Y was apparently unsuccessful. The scattergram plot of the data seen in Figure 5 does not indicate any substantial relationship between SOON area and Algonquin intensity. The mathematical formula determined gives even less hope of a relationship:

$$\text{CALSCN} = B (\text{SOONAREA}) + A \quad (9)$$

or

$$\text{CALSCN} = .00015 (\text{SOONAREA}) + 1.09429 \quad (10)$$

where

CALSCN = calibrated Algonquin scan value, and

SOONAREA = corrected area from the SOON histograms.

The correlation coefficient, r , was equal to .59932 with an r^2 of .35919. The correlation coefficient indicates how well a regression line characterizes the linear relationship between two variables while r^2 is a measure of the proportion of variance in one variable explained by the other and measures the strength of the relationship between the two variables (Ref 33:279).

At this point, it seemed reasonable that a better mathematical relationship could be found. Relying on techniques described by Neter and Wasserman (Ref 31:131-136), the plot depicted in Figure 5 seemed to indicate that the variance increases as X (SOONAREA) increases. Therefore, using their

technique for cases in which the standard deviation of the error terms in the regression equation is proportional to X , the following transformations were developed:

$$Y' = Y/X \quad (11)$$

$$X' = 1/X \quad (12)$$

so that

$$Y' = a + \beta X' + \epsilon \quad (13)$$

becomes the basic equation. In the two analysis programs, Equations (11) and (12) become

$$\text{NEWSCN} = \text{CALSCN}/\text{SOONAREA} \quad (14)$$

and

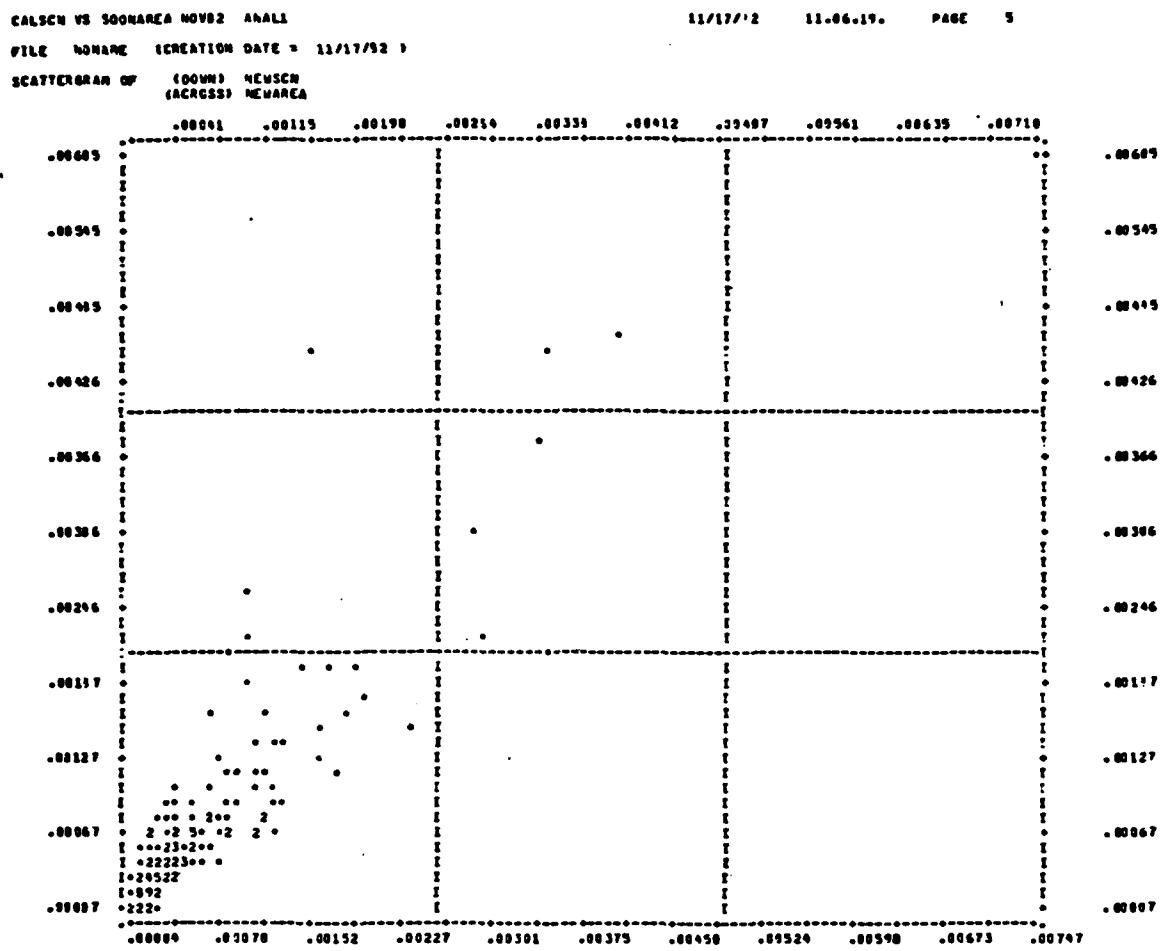

$$\text{NEWAREA} = 1/\text{SOONAREA} . \quad (15)$$

When these values were used in the SPSS regression routine a better correlation was established as shown in the scattergram in Figure 6. From this, the resulting equation for predicting an active region on the Algonquin scans with SOON data is:

$$\text{NEWSCN} = B (\text{NEWAREA}) + A \quad (16)$$

which, in the variables of interest, becomes

$$\text{CALSCN/SOONAREA} = B (1/\text{SOONAREA}) + A . \quad (17)$$

CALSCN VS SOONAREA NOV92 ANALY 11/17/92 11-04-19 PAGE 4

Figure 6. Scattergram of NEWSCN versus NEWAREA

The correlation coefficient for this relationship is .88509 giving an r^2 of .78338 which indicates that the regression equation defines a good relationship between the dependent (calibrated Algonquin scans) and independent (SOON corrected area) variables. Equation (17) can be simplified to

$$\text{CALSCN} = B + A (\text{SOONAREA}) \quad (18)$$

resulting in

$$\text{CALSCN} = .88782838 + .00025237604 (\text{SOONAREA}) \quad (19)$$

using the statistics provided in the SPSS program.

Confidence Interval

Equation (19) is good for point estimates but because the deviations from the line increase with large SOONAREA, the certainty associated with the point estimate becomes less for large SOONAREA. Therefore, in order to quantify the potential errors involved in using this equation, confidence limits must be established. The 95 percent prediction interval for values predicted with Equation (19) is found as follows (Ref 21:373-374):

$$\begin{aligned} \hat{Y}_o/X - t_{\alpha/2, n-2} \sqrt{\text{MSE}' [1 + 1/n + (X' - \bar{X}')^2/S_{xx}]} &\leq Y_o/X \\ \leq \hat{Y}_o/X + t_{\alpha/2, n-2} \sqrt{\text{MSE}' [1 + 1/n + (X' - \bar{X}')^2/S_{xx}]} \end{aligned} \quad (20)$$

where

$\hat{Y}_o/X = Y_o'$ = NEWSCN value predicted using Equation (16),

\hat{Y}_o = CALSCN value predicted using Equation (19),

X = SOONAREA observed,

Y_o = The true value of CALSCN,

$t_{\alpha/2, n-2} = t_{.05/2, 140} = 1.97$,

MSE' = Mean square error of the transformed data,

X' = Transformed X value for which CALSCN value is to be predicted,

\bar{X}' = Mean of transformed X values, and

$S_{xx'}$ = Corrected sum of squares of X of the transformed X
values = $(n-1)(s_x^2)$

which results in a confidence interval in terms of the original data of

$$\begin{aligned}\hat{Y}_o - t_{\alpha/2, n-2} \sqrt{MSE' [1 + 1/n + (X' - \bar{X}')^2 / S_{xx'}]} &\leq Y_o \\ \leq \hat{Y}_o + t_{\alpha/2, n-2} \sqrt{MSE' [1 + 1/n + (X' - \bar{X}')^2 / S_{xx'}]} &\quad (21)\end{aligned}$$

with

$$MSE' = .00019012 ,$$

$$\bar{X}' = .0007445 , \text{ and}$$

$$S_{xx'} = 141 (.0009306)^2 = .0001221083 ,$$

so the confidence interval becomes

$$\begin{aligned}\hat{Y}_o - 1.97 \sqrt{.00019012 [1 + 1/142 + (X' - .0007445)^2 / .0001221083]} &\leq Y_o \\ \leq \hat{Y}_o + 1.97 \sqrt{.00019012 [1 + 1/142 + (X' - .0007445)^2 / .0001221083]} &\quad (22)\end{aligned}$$

Equation (22) verifies that the width of the interval increases as X increases which corresponds to what is observed in the original data.

Equations (19) and (22) are consistent with the five assumptions expected of a linear regression model. The results indicate the sample was random, the dependent variable, Y, came from a normal distribution for any given value of X, and, after the transformation, the regression was linear, the

variation of Y was constant, and the random errors were independent.

Other Relationships

After reviewing the residual analysis performed on the data by the analysis program (See Appendix F), it seemed that at least one outlying data point may have been unduly influencing the regression equation. All together, there were six residuals greater than two standard deviations. These represented about five percent of the total and were expected, however, one point ($CALSCN = 3.04$, $SOONAREA = 668.29$) had a residual twice as great as the next largest residual. After rechecking the data reduction for this point and finding nothing wrong, it was decided to explore the effects of this point on the regression equation. The point was eliminated from the data and the programs were rerun. Equations (11) through (18) still apply only now the resulting equation is:

$$CALSCN = .869333787 + .00024499284 (SOONAREA) \quad (23)$$

which resulted in an r of .91565 and r^2 of .83842 on the transformed equation. The confidence limits for values predicted with this equation are:

$$\begin{aligned} \hat{Y}_o - 1.97\sqrt{.00012736[1+1/141+(X'-.0007391)^2/.0001215552]} &\leq Y_o \\ \leq \hat{Y}_o + 1.97\sqrt{.00012736[1+1/141+(X'-.0007391)^2/.0001215552]} & \end{aligned} \quad X \quad (24)$$

which has a derivation similar to Equation (22). Even though the linear association between the dependent and independent

variables, as measured by the correlation coefficient, is better than the original formulation, there is no valid reason to exclude the data point in question other than the fact that it is not typical of the rest of the data. For this reason, the model defined by Equations (19) and (22) is the best relationship found between the Algonquin scans and the SOON data. Note also that even with the point removed, Equation (23) does not differ appreciably from Equation (19).

To further explore the correspondence between the Algonquin scan values and the SOON data, a second set of data was developed from the original histogram records. Now, however, absolute brightness was calculated for each SOON region by multiplying each area by its bin value (relative brightness). Since each bin is linearly brighter than the preceding one, this should give a good indication of how active the region is. This means that the larger a bin area is, the greater its contribution to the overall brightness of the region which, in turn, should be reflected by a larger spike in the corresponding Algonquin scan. As expected, similar results were obtained with this method as in the first analysis and will not be pursued further here.

IV. Conclusions and Recommendations

Conclusions

From this analysis it is apparent that a relationship does exist between Algonquin drift scans of the sun and SOON histogram records of active regions on the sun. The area above the quiet sun level calculated from the SOON data can be used to predict the location and intensity of solar bursts in the 10.7 cm solar radio range as gleaned from the Algonquin scans of the sun. With further analysis, as recommended below, the SOON histograms could become a valuable tool in aiding the understanding of the relationship between solar active region area and the 10.7 cm solar flux.

Recommendations

In order to improve this analysis several important modifications to this experiment could be done to refine the results.

1. The ephemeris data used in the analysis could be modified to account for the fact that the tabulated values are for 0000Z while the Algonquin solar scans and SOON records were taken at 1700Z each day. Though these changes are small, at certain times of the year the angles do vary rapidly and could affect the accuracy of the data.

2. To use as much data as possible, corrections could be applied to those SOON data records with a wavelength offset

other than zero. Though few records have a wavelength offset other than zero, those that do could be significant and should not be wasted.

3. Further discussions with the SOON engineers and physicists might uncover better ways to categorize and quantify the histograms. In this study, the quiet sun value was used as a benchmark to determine what brightness levels (bin numbers) should be summed to get a rough idea of a region's brightness above the background value, thus making an inference as to the region's contribution to hydrogen-alpha wavelength, and, after regression, 10.7 cm flux. A better benchmark might be found such as using the flare threshold rather than brightness above quiet sun.

4. Data used in any follow on study must be standardized. The only data available for this study was in the May-December 1978 time frame. The SOON system was very new at the time and was going through considerable growing pains. This is reflected in the fact that data was not all standarized to the same quiet sun level (some was "standarized" to bin 10 while some was "standarized" to bin 12). If the same time frame is used, the data must all be standarized to the same level.

5. Though the Algonquin scans are supposed to be taken at 1700Z, they often slip one way or the other by as much as 20 minutes. Since the SOON data was only available at 1700Z, if this was the case, the data was compared as if both readings were taken at 1700Z. In the future, the times of both data sets should be matched exactly.

6. A study such as this might be expanded to try and find a relationship between SOON data and other wavelengths. Such studies would involve other SOON sites besides just Holloman, New Mexico.

7. In the future, data must be analyzed for a longer period. Though data from May through December 1978 was available, not all of it could be used. Future studies should expand to cover many months (6 or more) and even years rather than just 2 1/2 months, especially when many days are lost to weather and equipment problems. Additionally, as many regions as possible should be included each day. Finally, studies should explore any relationship between the solar cycle and these results, looking specifically at periods during solar maximum and solar minimum.

8. A more complex method should be investigated for determining the intensity of the Algonquin data than measuring the peak values. One possibility is to take an average value for each active longitude (as identified by a spike). Another would be to integrate the area under the curve.

9. Analysis should be done to perfect methods to predict the 10.7 cm solar flux using the Algonquin solar scans. Once this is done, based on the present study, SOON data could be used to predict the 10.7 cm solar flux.

FROM SPACE ENVIRONMENT SERVICES CENTER BOULDER COLO

SDF NUMBER 200

JOINT AFGWC/SESC PRIMARY REPORT OF SOLAR AND GEOPHYSICAL ACTIVITY ISSUED 2200Z 19 JULY 1974

IA. SOLAR ACTIVITY HAS BEEN VERY LOW WITH THREE NON-ENERGETIC SUBFLARES REPORTED DURING THE PAST 24 HOURS. REGIONS 438 (S08W72) AND 443 (S12E06) HAVE BEEN STABLE. MINOR INTENSITY FLUCTUATIONS HAVE OCCURRED IN REGIONS 442 (SLOW34) AND 445 (S04W37). AN ACTIVE PROMINENCE (S13E90) PARTIALLY ERUPTED, AND THEN TOTALLY DISSIPATED, BETWEEN 0715-0840Z. NO OTHER ACTIVITY HAS BEEN REPORTED TO SUBSTANTIATE AN ACTIVE RETURN OF OLD REGION 435.

IB. SOLAR ACTIVITY IS EXPECTED TO REMAIN LOW.

II. THE GEOMAGNETIC FIELD HAS BEEN QUIET. IT IS EXPECTED TO BE QUIET TO UNSETLED.

III. EVENT PROBABILITIES 20 - 22 JULY

APPENDIX B

Algonquin Videometer Scan and Calibration Levels

The following videometer scan (Figure 7) is typical of the data received from the Algonquin Radio Observatory. These same scans are reproduced in Solar Geophysical Data (May 1978-July 1978) in a much smaller format. The east and west limbs of the solar disk are annotated on the graph and the point halfway between these points gives an approximate indication of the Central Meridian location. Based on this data, rough correlations with longitude could be made with active regions identified by the SOON data. The spikes on this graph represent longitudes with higher than normal activity. The horizontal baseline is for reference only and had to be adjusted slightly to standardize all of the plots. Adjustments took the form of adding or subtracting a small correction from the plot readings if the scan did not start precisely on the baseline. These readings were then further standardized by applying the daily calibration constants listed in Table 2.

APPENDIX C

SOON Card Format

The SOON data was received on punched cards. A region identifier record format is shown first. These cards are used by the SOON scientists to identify regions to be observed by the SOON telescopes and give region identifying information that is inherent in each of the histograms which follow for that region. Following this is the format for the SOON histogram data sets. The basic card layout is specified and then an example card image is presented. The SOON program outlined in Appendix D follows this format to reduce the data.

FORMAT FOR REGION IDENTIFIER RECORDS

| COLUMN | PARAMETER | DESCRIPTION |
|---------|-----------|---|
| 1 | ICONT | CONTINUATION CODE |
| 2 | NOBS | OBSERVATION CODE |
| 3-6 | IDENT | RGN # or RGDF |
| 7-8 | MTIME(1) | YEAR |

APPENDIX D

SOON Program

The following program reduced the SOON histogram inputs into a usable and comparable form. The data was received on punched cards in the format depicted in Appendix C. The hundreds of data records involved were run through the program and outputted in the tabular format described in the text. Comments are included in the program to document what is occurring at each point. Many of the operations performed may seem redundant but they were left in this format so each could be readily identified and as an aid to clarity. Appendix E contains a detailed explanation of the coordinate transformation used to get the data into a common reference frame.

APPENDIX E

Coordinate Transformation

This coordinate transformation algorithm was used in the SOON Program to transpose the latitude and longitude from the SOON coordinate frame to the Algonquin frame to aid in direct comparison of the data. X, Y, Z is the heliocentric frame. The east-west frame is x, y, z.

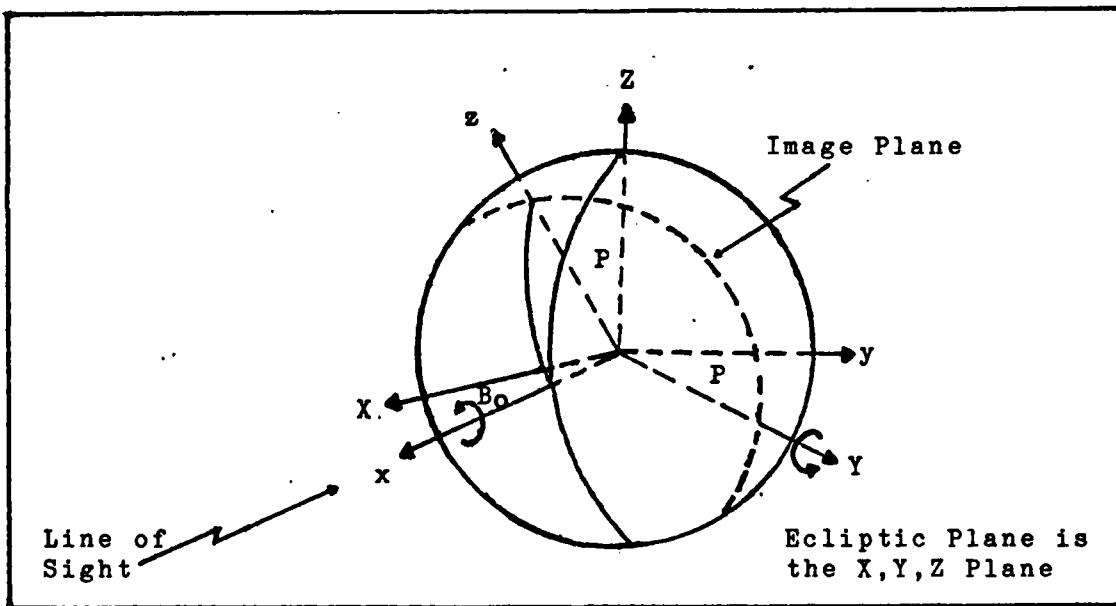

Figure 11. Frame Orientations

Rotations

The first transformation is a positive or negative rotation about Y by an angle B_0 .

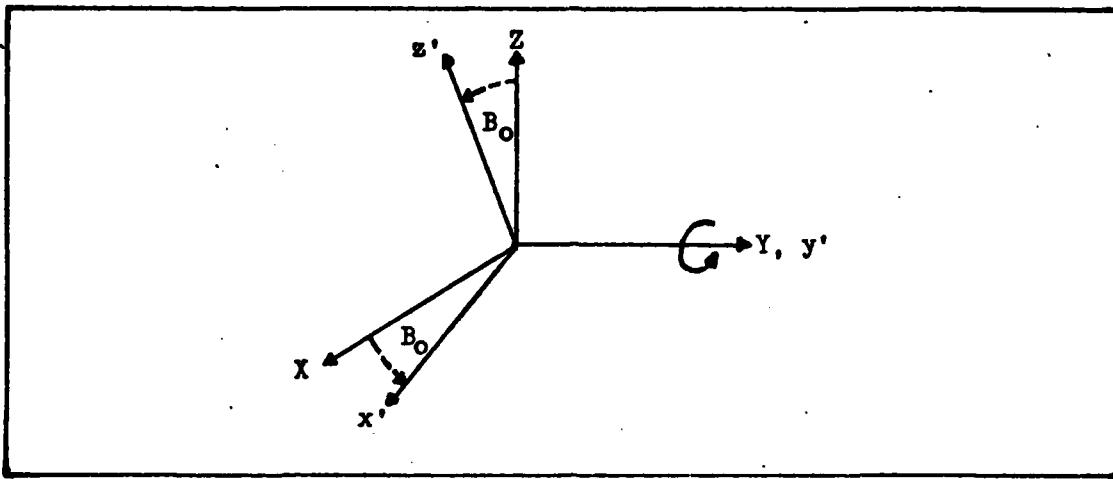

Figure 12. Rotation about Y

The second transformation is a positive or negative rotation about x by an angle P (Ref 25:8-13).

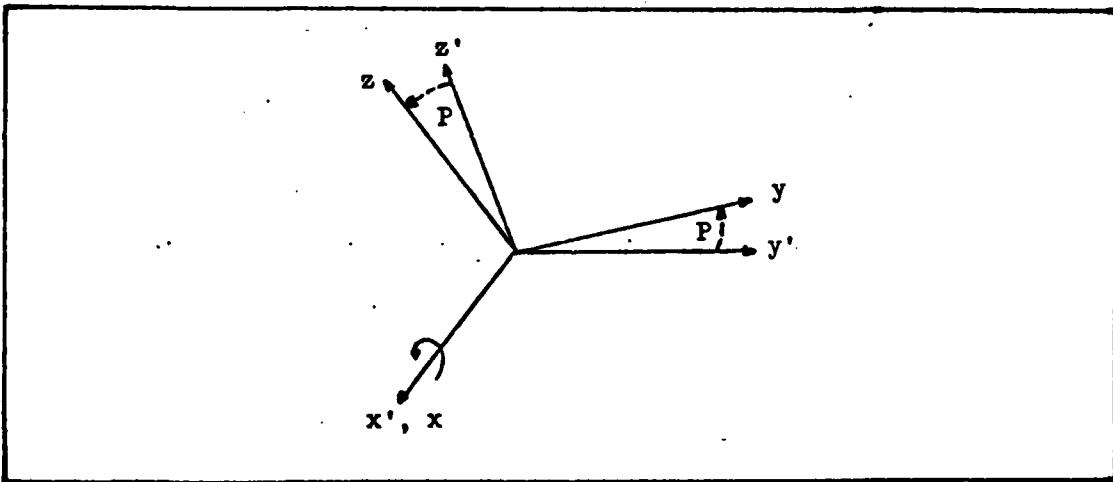

Figure 13. Rotation about x

Orthogonal Transformations

For two positive rotations:

$$\begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \begin{bmatrix} \cos B_o & 0 & -\sin B_o \\ 0 & 1 & 0 \\ \sin B_o & 0 & \cos B_o \end{bmatrix} \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \gamma \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (25)$$

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos P & \sin P \\ 0 & -\sin P & \cos P \end{bmatrix} \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} = \beta \begin{bmatrix} x' \\ y' \\ z' \end{bmatrix} \quad (26)$$

therefore,

$$\begin{bmatrix} x \\ y \\ z \end{bmatrix} = \beta \gamma \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \alpha \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (27)$$

where

$$\alpha = \begin{bmatrix} \cos B_0 & 0 & -\sin B_0 \\ \sin P \sin B_0 & \cos P & \sin P \cos B_0 \\ \sin B_0 \cos P & -\sin P & \cos P \cos B_0 \end{bmatrix} \quad (28)$$

To obtain X, Y, and Z a spherical to rectangular coordinate transformation must be done (Ref 34:36)

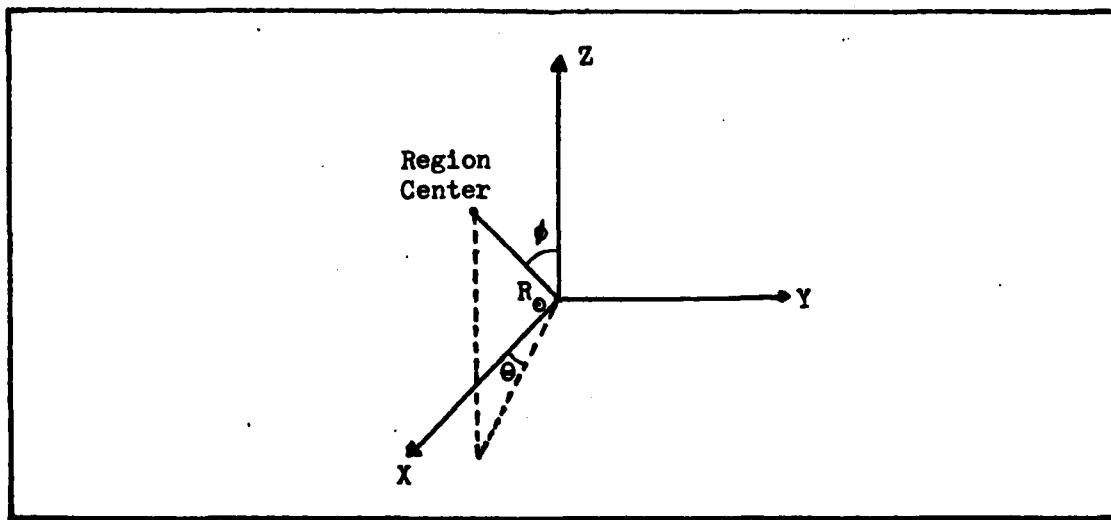

Figure 14. Spherical to Rectangular Coordinate Transformation

such that

$$\begin{aligned} X &= R_e \sin \phi \cos \theta \\ &= R_e \cos (L_r) \cos (\Lambda_r) \end{aligned} \quad (29)$$

where

R_e = radius of the sun,
 L_r = heliocentric latitude of the region on the sun, and
 Λ_r = central meridian angle (heliocentric).

Similarly,

$$Y = R_e \cos (L_r) \sin (\Lambda_r) \quad (30)$$

and

$$Z = R_e \sin (L_r) \quad (31)$$

Therefore,

$$x = \cos B_o R_e \cos (L_r) \cos (\Lambda_r) - \sin B_o R_e \sin (L_r) , \quad (32)$$

$$\begin{aligned} y &= \sin P \sin B_o R_e \cos (L_r) \cos (\Lambda_r) \\ &\quad + \cos P R_e \cos (L_r) \sin (\Lambda_r) \\ &\quad + \sin P \cos B_o R_e \sin (L_r) , \end{aligned} \quad (33)$$

and

$$\begin{aligned} z &= \sin B_o \cos P R_e \cos (L_r) \cos (\Lambda_r) \\ &\quad - \sin P R_e \cos (L_r) \sin (\Lambda_r) \\ &\quad + \cos P \cos B_o R_e \sin (L_r) \end{aligned} \quad (34)$$

The data was unitized to solar radii by setting $R_e = 1.0$.

To go back to latitude and central meridian angle in the east-west frame, a rectangular to spherical transformation is performed:

$$\tan \lambda_r = y / x \quad (35)$$

then

$$\lambda_r = \tan^{-1}(y / x), x \neq 0 \quad (36)$$

and

$$\cos(90 - \iota_r) = z / \sqrt{x^2 + y^2 + z^2} \quad (37)$$

therefore

$$\iota_r = 90 - \cos^{-1}[z / \sqrt{x^2 + y^2 + z^2}] \quad (38)$$

where

λ_r = east-west frame central meridian angle (longitude)

and

ι_r = east-west frame latitude.

In the SOON Program

x = LOS (line of site), and

y = STORE (I,9).

APPENDIX F

Data Analysis Programs

The following programs, ANAL1 and ANAL3, were used to analyze the data for this project. ANAL1 provides a scattergram of the data while ANAL3 gives a more complete breakdown of the results of the analysis including the residuals used to determine the adequacy of the model. These basic programs, with minor modifications, were used to test the data after removing some of the data points. ANAL3 was used to find more significant digits for the predictive equations by multiplying each NEWSCN and NEWAREA value by 1000 on one run.

VITA

Craig Anton Puz was born on 24 June 1954 in Pasadena, California. He graduated from Edgewood High School in West Covina, California, in 1972 and attended the United States Air Force Academy, Colorado Springs, Colorado, from which he received the degree of Bachelor of Science in General Studies in June 1976. Upon graduation he reported to the 90th Strategic Missile Wing at F. E. Warren Air Force Base, Cheyenne, Wyoming, where he served as a Minuteman III Missile Combat Crewmember, Training Division instructor, and Emergency War Order instructor. While at F. E. Warren, he also earned a Master of Business Administration degree through the Air Force Institute of Technology sponsored, University of Wyoming masters program. He served at F. E. Warren until entering the School of Engineering Space Operations masters program, Air Force Institute of Technology, in 1981.

| 20. ABSTRACT (Continue on reverse side if necessary and identify by block number) Using a statistical regression model, a relationship was found between the area of solar active regions (bright in hydrogen-alpha, $\lambda = 6562.8 \text{ \AA}$ in the visible) and their 10.7 cm radio emission. Data used in this analysis were the brightness-area histograms obtained from the Solar Observing Optical Network (SOON) and daily drift scans obtained from the Algonquin Radio Observatory, Ottawa, Canada. This data, for the period 1 May through 16 July 1978, was used to develop the following relationship: Algonquin Scan Peak Value = .88782838 + .00025237604 (Calibrated SOON Area) | | |
